ABSTRACT

We use data from the Transiting Exoplanet Survey Satellite (TESS) to search for, and set limits on, optical to near-infrared photometric variability of the candidate James Webb Space Telescope (JWST) spectrophotometric standards. Our search of 37 of these candidate standards has revealed measurable periodic variability in 15 stars. The majority of those show variability that is less than half a percent; however, four stars are observed to vary photometrically, from minimum to maximum flux, by more than 1% (the G dwarf HD 38949 and three fainter A dwarfs). Variability of this size would likely impact the error budget in the spectrophotometric calibration of the science instruments aboard JWST. For the 22 candidate standards with no detected variability, we report upper limits on the observed changes in flux. Despite some systematic noise, all stars brighter than 12^{th} magnitude in the TESS band show a 3σ upper limit on the total change in brightness of less than half a percent on time scales between an hour and multiple weeks, empirically establishing their suitability as spectrophotometric standards.

Keywords: variable stars, white dwarfs, calibration

1. INTRODUCTION

The James Webb Space Telescope (JWST), an in-25 frared space telescope with a diameter of 6.5 m, promises 27 to revolutionize many areas of astrophysics, from exo-28 planets to the most distant galaxies (Kalirai 2018; Gard-29 ner et al. 2006). In order to accomplish those goals, $_{30}$ JWST will observe a sample of spectrophotometric stan-31 dard stars to calibrate observations across the near- and $_{32}$ mid-infrared (0.6–28.8 μ m). The objective is an accu-33 racy in the observed flux of the standard stars to bet-34 ter than 2% (see JWST Data Absolute Flux Calibra-35 tion in JWST User Documentation 2016). A successful 36 standard-star calibration program will not only enable $_{\rm 37}$ the absolute calibration and the JWST cross-instrument 38 calibration, but will also tie JWST observations to other 39 space telescopes, such as Hubble, Spitzer, and WISE, 40 and other ground-based observatories.

The selection of standard stars must take into account 42 many factors that can reduce both the accuracy and the 43 precision of the spectrophotometric calibration. The list 44 of possible reasons to reject potential standards during 45 the vetting process is long, but among them, variability 46 is always a red flag. Variable stars should be avoided 47 because their variations will increase the noise in the 48 calibration data. Even low-amplitude variability below 49 any level of direct concern could point to more subtle 50 concerns, such as binarity, pulsation, strong magnetic-51 field activity, or the presence of circumstellar material 52 (Bohlin et al. 2014). Each of these issues is a rea-53 son in itself to reject a candidate, but may have oth-54 erwise gone unnoticed. The identification of any known 55 variable stars prior to their observation by JWST will 56 give the calibration team the opportunity to investigate 57 them more closely and potentially save valuable observ-58 ing time. Optimizing the calibration of JWST will con-59 tribute to the success of NASA's flagship mission.

High-cadence photometric surveys of stars, as done 61 by missions like CoRoT (Auvergne et al. 2009), Kepler 62 (Koch et al. 2010) and TESS (Ricker et al. 2015), has 63 revealed that they can change brightness due to a va-64 riety of factors, and these variations can unexpectedly 65 change in timescale or amplitude. Many of these vari-66 ations are internal to the star, e.g. stellar pulsations 67 or spots rotating in and out of view (e.g. Breger 1979; 68 McQuillan et al. 2014), while other variations are ex-69 ternal, e.g. eclipses and transits (e.g. Prša et al. 2011; 70 Thompson et al. 2018). Time-series photometric obser-71 vations have revealed many examples of atypical bright-72 ness variations where stars change brightness suddenly 73 and in unexpected ways. For example, Boyajian's star, 74 KIC 8462852, was discovered using Kepler data and 75 shows unexplained drops in the flux of the star as large 76 as 20% at seemingly random times (Boyajian et al. 77 2016). The nearby red supergiant Betelgeuse dimmed 78 by more than one visual magnitude in 2019, the deepest 79 decline reported in 50-plus years of observations (Mon-80 targès et al. 2021; Cotton et al. 2020). Some white dwarf 81 stars, the classic choice for photometric standards in the 82 UV and optical, have shown both unusual intrinsic vari-83 ability from pulsations (e.g. Provencal et al. 2009; Kilic 84 et al. 2015; Hermes et al. 2017) and external variability 85 caused by accretion disks (Scaringi et al. 2021) or dis-86 integrating planetesimals (as large as 40%; Vanderburg 87 et al. 2015; Guidry et al. 2021). While these examples 88 are rare, they demonstrate that stars can vary for a vari-89 ety of reasons, many of which are not predictable based on current knowledge.

TESS is well positioned to monitor the candidate standards for JWST for changes in flux on time scales between minutes and weeks at a precision as fine as a few hundred parts per million (Ricker et al. 2015), an improvement in precision, cadence and coverage over previous observations to identify short term variability in standard stars from the ground (e.g., Marinoni et al. 2016). TESS was launched in 2017 with the purpose of identifying transiting exoplanets around nearby stars. It photometrically observes a swath of sky covering 24 degrees by 90 degrees for a month at a time and has a bandpass of 0.6–1 μ m (Ricker et al. 2015) that overlaps with the shortest wavelengths of the JWST bandpass.

As a result, TESS has serendipitously observed most of the candidate spectrophotometric standards for

106 JWST over the course of its mission, and it will continue to do so in its extended mission. We have examined the TESS data for these candidates, looked for evidence of photometric variability, and we report upper limits on any variability if none was detected. For the 15 candidate spectrophotometric standards found to show statistically significant periodic variability, we show a light curve and periodogram, and provide a few basic statistics describing the amplitude of the variations.

2. CANDIDATE JWST SPECTROPHOTOMETRIC STANDARD STARS

Spectrophotometric calibration requires accurate models of the stars chosen as standards, because any errors in the assumed true spectrum of a standard will propagate into the entire calibrated database (e.g. Cole hen et al. 1992; Price et al. 2002; Sloan et al. 2015). Calibrating with a sample of standards will reduce the impact of problems with the model of any one star, and combining different types of standards will reduce the problems even further. By comparing the calibration as determined from different stars, and different classes of stars, outliers can be identified and their models corrected, or, if that proves impossible, the stars can be rejected.

The JWST calibration will be based on three classes 131 of standard stars: white dwarfs, A dwarfs, and solar analogs (i.e., G dwarfs) (Gordon et al. 2022). It is ex-133 pected that a minimum of five stars of each class will be 134 observed during the JWST mission to accomplish this 135 task. Comparisons of the stars will identify potential is-136 sues with models of the stars and possible outliers. The 137 sample examined in this paper, see Table 1, is based on 138 lists of candidates available in the JWST User Documen-139 tation accessed in 2020 December¹ (JWST User Docu-140 mentation 2016). It must be stressed that the candidate 141 list is evolving as stars are vetted and new stars are 142 added to better cover parameter space (Gordon et al. 143 2022). The calibration standard stars in this list over-144 lap calibration stars used by other observatories. For 145 example, the list includes A dwarf stars reported by Reach et al. (2005) to be primary standards for IRAC on 147 Spitzer (see those with shortened names starting with J 148 in Table 1). For more information on how the calibration stars are selected, see Gordon et al. (2022).

3. TESS OBSERVATIONS

To study the variability of the candidate spectrophoto-152 metric standards, we use observations from TESS span-153 ning Sectors 1 to 40 (years 2017–2021). When pos-154 sible, we utilize the 2-minute cadence data processed 155 by the Science Processing Operations Center (SPOC) 156 pipeline, which provides high-quality background subtraction, systematic correction and flux-dilution correc-158 tions due to the large pixel scale of TESS (Smith et al. 159 2020a; Clarke et al. 2020; Morris et al. 2020; Smith et al. 160 2020b). A few of our candidate stars were only observed by TESS in the Full Frame Images (FFIs). For these tar-162 gets, we only report on their variability if MAST hosts 163 TESS-SPOC high-level science products (Caldwell et al. 164 2020), since these are similarly processed by the SPOC 165 pipeline and have corrections applied for crowding due 166 to the large TESS pixels. These FFIs store data on the stars at a 30-minute or 10-minute cadence, depending on when the data were collected. See Table 1 for a list of 169 those targets used in our analysis, including their TESS 170 Input Catalog (TIC) identification and magnitude (Stas-171 sun et al. 2018). All of the data is available at MAST: 172 DOI 10.17909/t9-tkr5-6a83.

Regardless of the data's cadence, we use the pre-search data conditioned, simple aperture photometry (PDC-175 SAP) photometric time series (Smith et al. 2020b) for our analysis. As an overview, the TESS pipeline that creates these light curves removes the background, per-178 forms simple aperture photometry using a fixed aperture that optimizes the signal-to-noise of the light curve, and then removes systematics by fitting Principal Component Analysis (PCA) basis vectors that represent common signals observed in nearby stars (Smith et al. 2012; Stumpe et al. 2012).

We then use the software lightkurve (Lightkurve 185 Collaboration et al. 2018) to detrend and normalize the 186 light curve. For some light curves we remove obvious 187 systematic variations by applying a Savitzky-Golay fil-188 ter (Savitzky & Golay 1964) with a window length of half 189 of the number of data points in the sector. As a sector 190 is \approx 27 days long, we only expect to be able to unequiv-191 ocally measure variability with time scales shorter than 192 half the length of the sector. Variability longer than 193 this time scale, unless very large in amplitude, is of-194 ten mistaken for systematics and is commonly removed 195 from the time series. While TESS data can be used 196 to find longer-period trends, it requires very careful ex-197 amination of possible systematic noise and stitching to-198 gether consecutive sectors of data. For this study we re-199 strict our analysis to repeatable variability of time scales 200 shorter than $\approx 13 \,\mathrm{days}$ in length and large-amplitude, 201 single-occurrence variations (such as eclipses or flares). To look for periodic variations, we used Lomb-Scargle 203 periodograms (Lomb 1976; Lightkurve Collaboration 204 et al. 2018) and report those with significant peaks that 205 otherwise do not appear to be caused by systematic 206 noise (see Section 3.1). For those with no significant 207 variability, we provide upper limits to any variability

3.1. Stars with Variability

208 that could be detected (see Section 3.4).

We found 15 of the JWST spectrophotometric stanlarger than 1% when considering the full exlarger than to maximum
larger than to maximum brightness, or peak-to-peak). For each variable star,
larger than the larger than the noise level
larger than the noise level
larger than the periodogram (Kjeldsen & Bedding 1995; Baran &
larger than the light curve
larger than the light curve
larger than Lomb-Scargle periodogram created from one entire

TESS sector for the 15 variable stars in our sample (two sectors for the case of HD 38949). Figure 2 highlights the four with the largest variations.

Table 2 summarizes the amplitude of the variations and their approximate period. It lists the period and amplitude of the maximum amplitude peak in the periodogram. Since most stars have more than one period of variability, the maximum amplitude in the periodogram does not capture the full change in relative flux observed in the TESS light curves. To approximate full observed peak-to-peak variability in the presence of noise, we calculate the quantity V_{95} , which is defined to be the difference between the maximum and minimum values of those points contained by 95.45% of the values in the light curve centered on the median. V_{95} measures the envelope of all data within $\pm 2\sigma$ of the median.

When reporting the statistics we use the sectors shown 238 in Figures 2-5 and bin the light curves to 6-minute 239 bins to improve the signal-to-noise ratio in some of the 240 dimmer stars. The displayed sectors were chosen to 241 represent the observed variability and have the lowest $_{242}$ observed noise. The V_{95} statistic acts as a reasonable 243 measure of the full amplitude of the observed variability for those whose amplitudes are significantly larger 245 than the noise. For the fainter stars with low ampli-246 tudes and noisy light curves, V_{95} overestimates the true 247 extent of the observed variability. For example, for the ²⁴⁸ dim variable star, J1732526 ($T_{mag} = 12.5$), the preci-249 sion on the flux (estimated from the average power in the periodogram, Kjeldsen & Bedding 1995) is 0.5%, one V_{95} fifth of the V_{95} statistic for this star. No single statistic ²⁵² will fully summarize the variability of these stars; the 253 light curves and periodograms provide a more complete 254 picture of the amplitude, timescale and shape of the ob-255 served periodicity.

A single TESS pixel covers more than 21 arcsec of 257 the sky on a side and the full-width-half-max ranges 258 from 1.13–2.76 pixels (Oelkers & Stassun 2018), making 259 it possible for nearby sources to contaminate our light 260 curves. As a way to quickly assess the impact of nearby sources, Table 2 includes the crowding metric calculated ₂₆₂ by the SPOC pipeline. This metric indicates the fraction 263 of the light in the aperture that comes from the target 264 star given the positions and amplitudes of stars in the ²⁶⁵ TIC. A value near 1.0 indicates an isolated star, while 266 lower values indicate significant crowding from neigh-267 bors. Two of our large-amplitude variables (J1732526 268 and J1812095) have crowding values around 0.8. The ²⁶⁹ SPOC Pipeline corrects the light curve amplitudes for 270 any dilution due to nearby stars by using this crowding 271 value (Fausnaugh et al. 2018). As a result, the am²⁷² plitudes and upper limits we report in this paper have ²⁷³ already accounted for these neighbors.

Due to the presence of nearby stars for two of our 275 large variables, we investigated the false positive sce-276 nario that one of the nearby stars is varying instead of 277 the target of interest. To test this possibility, we use 278 the code TESS_Localize (Higgens & Bell 2022) to de-279 termine if the location of the observed variations in the 280 pixel time series is consistent with the position of the 281 target star, as reported by Gaia Data Release 2 (Gaia ²⁸² Collaboration et al. 2018). We analyzed the large ampli-283 tude frequencies from Sector 40 data for both J1732526 ²⁸⁴ and J1812095. The heat maps of per-pixel amplitudes 285 shown in Figure 1 for J1732526 were calculated using 286 the five largest frequencies and the two largest frequen-287 cies for J1812095 apparent in the periodogram. These 288 per-pixel amplitudes are then fit to the TESS pixel re-289 sponse function (PRF) to obtain the true location of 290 the variability. In both cases the location on the CCD 291 of the largest amplitudes overlaps with our target star. ²⁹² For completeness, we analyzed all 15 variable stars sim-293 ilarly, despite having no bright, nearby sources. In no 294 case did evidence emerge that a nearby source caused 295 the variations, though for many stars with less signifi-296 cant variability, it was not always possible to convinc-297 ingly extract and fit per-pixel variability.

3.2. Reasons for Variability

While we do not attempt to definitively explain the physical reasons for the variability we observe in these stars, it is likely the reason for the photometric variability ity is related to either stellar pulsations or spots.

Many of our variable stars are A dwarfs. Variability 304 in A-type stars can occur due to a plethora of reasons, 305 including stellar pulsations. The δ Scuti variables ap-306 pear at the intersection of the instability strip and the 307 main sequence (e.g., Petit 1987). They are the most 308 prominent pulsators among A dwarfs, and they make up $\approx 27\%$ of all variable A and F dwarfs (Uytterhoeven et al. 310 2011). They pulsate in pressure modes and mixed pres-311 sure and low-order gravity modes due to the κ mechanism (Lee 1985), with pulsation frequencies in the range 313 18 min to 8 hrs (Amado et al. 2004). γ Doradus vari-314 ables also appear in a similar part of the HR diagram 315 (e.g., Kaye et al. 1999), although they are rarer than ₃₁₆ δ Scuti stars, making up $\approx 12\%$ of all variable A and F dwarfs. (Uytterhoeven et al. 2011). γ Dor variables pul-318 sate in non-radial, high-order gravity modes caused by 319 convective blocking (Guzik et al. 2000) with pulsation 320 periods typically on the order of one day (Grigahcène $_{321}$ et al. 2010). Some stars, known as hybrid γ Dor- δ Scuti

NOTE—The column Period gives the period of the largest amplitude peak (max Amp.) seen in the periodogram. V_{95} is the peak-to peak range encompassing 95.45% of the binned observed relative fluxes. Errors on the max Amp. value are less than 0.002% with the exception being the 'J' stars ($T_{mag} \ge 11$) whose errors are near 0.01%.

[†]CROWD comes from the CROWDSAP estimate from the TESS SPOC pipeline and is the fraction of flux from the target in the extracted aperture.

 $_{322}$ stars, exhibit both γ Dor and δ Scuti pulsations (Gri- $_{323}$ gahcène et al. 2010). These hybrid pulsators account for $_{324}$ an additional $\approx 23\%$ of all variability found in A and F $_{325}$ dwarfs. In our sample we find evidence of all three types $_{326}$ of the above pulsators at varying amplitudes.

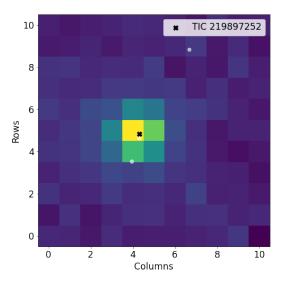

Other than pulsations, binarity and rotational modu-328 lation due to spots can also cause variations in A stars. 329 In our sample, we do not find evidence of short-period, 330 eclipsing binarity which is expected since these usually 331 have large flux variations that would have been seen 332 in previous observations. Regarding rotation, Balona (2013, 2017) claim to have found spots in more than 50% 334 of A stars in the Kepler data, suggesting that modula-335 tion due to surface rotation is more commonly observed than previously thought. However, the origin of spots in 337 A and B stars is currently under debate, as these stars 338 do not have a significant surface convective zone, which 339 is usually associated with surface spots. The presence of a fossil magnetic field (Parker 1955) and the creation 341 of a magnetic field caused by a dynamo effect in mass 342 motions that occur in convective layers (Charbonneau 343 2014) are two of the contending ideas for the creation 344 of spots in hotter main sequence stars. In our sample,

 $_{345}$ we find signatures that suggest the presence of spots in $_{346}$ several objects: HD 38949, J1812095, λ Lep, η^1 Dor, $_{347}$ and HR 7018.

3.3. Large Amplitude Variable Stars

In this section we discuss in more detail the size and astrophysics for the variability of the six stars with the largest changes in brightness that we measured in the TESS data from our target list. Each of these stars show a $V_{95} \geq 0.35\%$. In these cases, the time scale and amplitude of the variations could impact high precision spectrophotometric calibrations, and their variability should be considered before using them as a standard star. The remaining nine stars have small enough amplitudes that at least for JWST they will not significantly impact the calibrations.

Three of the large-amplitude variable stars are A dwarfs from the Reach et al. (2005) Spitzer calibration. The amplitudes we see here were likely below the level of detection for Spitzer. For comparison, Krick et al. (2021) measured the IRAC fluxes in dozens to thousands of observations for most of our variable stars and reported standard deviations between 0.7% and 2.8%

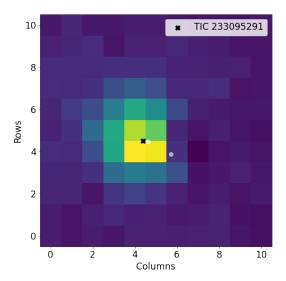

Figure 1. Heat maps of the fitted amplitudes for each 21 arc second pixels at the observed periods across the pixels downloaded from TESS in Sector 40 for this target (generated by TESS_Localize Higgens & Bell 2022.) TIC 219897252 (J1732526) is on the left and TIC 233095291 (J1812095) is on the right. The grey circles represent known Gaia Data Release 2 sources with $T_{mag} > 15$, approximately three magnitudes dimmer than the target stars. The black 'x' represents the best fit between the heat map and the TESS PRF. In both cases the best fit location overlaps the Gaia location of our target at the center of the TESS pixels, indicating that the variability comes from the targeted source.

 $_{367}$ for the 3.6 μm band. This observed scatter is approximately four times larger than the variability we report $_{369}$ here.

be used to support flux calibrations of other observatories.

3.3.1. HD 38949 (TIC 32869782)

This G dwarf $(T_{mag} = 7.3)$ varies with a peak-to-peak 371 amplitude of 1.2% (Figure 2, top panel). TESS observed 373 HD 38949 in Sectors 6, 32, and 33. The power spec-374 trum is complex and shows a 7.9-day peak along with 375 peaks at both a half and quarter of that period. This 376 quasi-periodic, oscillatory behavior is consistent with a combination of stellar rotation at a 7.9-day period and 378 migrating star spots on the surface due to strong mag-379 netic activity (Santos et al. 2021). HD 38949 is also 380 an x-ray source, as revealed by the Swift Observatory (Evans et al. 2020, 2019), which supports a picture of 382 active spots and flares. Due to these properties, the JWST calibration team has already removed this star 383 from the list of standards (Gordon et al. 2022).

It is also noteworthy that HD 38949 is listed in the Hubble Space Telescope Calspec database² (Bohlin et al. 287 2014) as a star with complete STIS coverage that could

3.3.2. J1808347 (TIC 219114641)

This A dwarf ($T_{mag}=11.9$) shows a rich set of peaks in its periodogram that produce a peak-to-peak amplitude of 1.65% (Figure 2, second panel). These variations compromise its ability to act as a spectrophotometric standard. The periods range from 0.5 to 1.0 hours, with the strongest mode at 0.6 hours. The high-frequency variations are caused by δ Scuti pulsations. The variability is difficult to see in the 30-minute TESS data taken during the first year of TESS observations; however, they are more apparent in the 2-minute cadence data from Sectors 40 and 41. This star will be observed again by TESS in Sectors 47–55.

3.3.3. J1732526 (TIC 219897252)

J1732526 is an A dwarf ($T_{mag}=12.5$) that behaves much like J1808347; it is multiperiodic, with its strongest mode having a period of 0.5 hours, suggesting most of the variability arises from δ Scuti pulsations (Figure 2, third panel). Its light curve has a peak-to-peak amplitude of roughly 1.4%, limiting its value as a spectrophotometric standard. However, in this case, this statistic is somewhat inflated by the inherent noise

 $^{^2}$ https://www.stsci.edu/hst/instrumentation/ reference-data-for-calibration-and-tools/astronomical-catalogs/ calspec

461

503

 412 of this dim object. The combined amplitudes of the 413 largest peaks point to a peak-to-peak variation closer 414 to 1%. In addition to the roughly 0.5-hour pulsation 415 modes, the light curve also shows a longer-period com- 416 ponent (roughly 2.5 days). This latter component could 417 arise from rotation, or it could indicate that J1732526 418 is a hybrid δ Scuti (p-mode) – γ Doradus (g-mode) pul- 419 sator. TESS observed this star at a 2-minute cadence in 420 Sectors 40 and 41 and is planning to observe it again in 421 Sectors 48–55.

3.3.4. J1812095 (TIC 233095291)

422

438

This A dwarf ($T_{mag} = 11.6$) shows consistent oscillations with periods of 1–3 days and peak-to-peak changes in the flux greater than 1.5% in the TESS bandpass (Figure 2, bottom panel). The light curve and periodogram show significant (though somewhat variable in amplitude) variations at a period of 2.44 days, with a secondary peak at exactly half that period, which indicates rotational modulation due to spots. The periodogram shows no evidence for short-period peaks (i.e., for periods of an hour or less). TESS observed this star in Sectors 14–26 at a 30-minute cadence, and at a 2-minute cadence in Sector 40. The variability is approximately the same across all sectors. The large peak-to-peak variability on long time scales may make this target unsuitable for high-precision spectrophotometric calibration.

3.3.5. HR 6514 (TIC 198456033)

The periodogram of this bright A dwarf ($T_{mag}=6.4$) shows a complex set of peaks with periods between roughly 0.5 and 2.0 hours, with up to 0.42% peak-to-peak variability (Figure 3, top panel). The strongest mode has a period of 1.3 hours. The periodicity is too fast to arise from stellar rotation and thus likely arises from short-period, δ Scuti (p-mode) pulsations. TESS observed this star in Sectors 14–26 and 40–41, and is expected to observe it again in Sectors 47–55. In the present data, the variability is consistent in amplitude from one sector to the next.

3.3.6. \(\lambda\) Lep (TIC 442871031)

This B9.5 dwarf ($T_{mag}=4.6$) varies with a coherent period of 1.26 days and multiple, exact harmonics of this base period, which suggests that the variation is due to spots on the stellar surface. The peak-to-peak amplitude is greater than 0.3% (Figure 3, bottom panel). TESS observed this star in two sectors: 5 and 32. In both sectors the variability was similar in amplitude and shape. λ Lep is one of the hot B dwarfs under consideration for use as standards starting in JWST Cycle 2 (Gordon et al. 2022).

3.4. Not Observed to Vary

We find no significant variability in 22 of the 37 stars we examined with existing TESS data. Figure 6 displays 464 the light curves and periodograms for three well-known 465 calibration stars with no significantly detected variabil-466 ity. We note that TESS commonly has large-amplitude 467 systematic noise in its light curves at long periods, in-468 cluding noise at periods of 2 weeks due to the orbit of 469 the spacecraft and near 1 day due to scattered light from 470 the rotation of the Earth (Luger et al. 2019). Our sam-471 ple of variable stars does not include those stars that 472 only showed evidence of these types of systematic noise. For those cases with no significant variability, we pro-474 vide two statistics to better understand the upper limits 475 of variability that could exist undetected in the TESS 476 data in Table 3. The photometric precision achieved by 477 the TESS data is mostly driven by the brightness of the 478 star, though in some cases systematic noise is playing $_{\mbox{\tiny 479}}$ a part. The quantity $A_{<1d}^{max}$ is the maximum amplitude 480 peak in the periodogram seen at periods less than 1 day. 481 This statistic can serve as measure of the upper limit 482 on consistent, short-period variability. $V_{99.7\%}$ can be in-483 terpreted as the largest peak-to-peak variation on time 484 scales longer than 30-minutes that could be present in 485 the data without detection. It is calculated by binning 486 the light curve to a 30-minute cadence and reporting the 487 difference between the minimum and maximum relative 488 flux for those points that lie within 99.7% of the median 489 observed flux. If the data are predominantly Gaussian 490 noise, this value is approximately six times the size of 491 the standard deviation of the light curve. For both of 492 these statistics we report the sector that gives the small-493 est value, as some TESS sectors are noisier than others 494 depending on scattered light from the Earth and Moon. TESS is able to provide limits to changes in bright-496 ness below 1% for all but six stars, all of which are dim-497 mer than 12.9 mag in the TESS band. For all but our 498 dimmest star, TESS sees no evidence of coherent, pe-499 riodic variability with amplitudes larger than 0.2% for 500 periods shorter than 1 day. Thus, TESS can still confirm 501 the suitability as flux standards of many of the faintest 502 sources in our sample.

4. CONCLUSIONS

The high-cadence, all-sky photometric survey of bright stars produced by TESS is a useful resource to vet potential spectrophotometric calibration stars for variability on time scales of a few minutes to a couple of weeks. The precise relative photometry, month-long stares, and fast cadence provided by TESS is a significant improvement over previous efforts to vet these stars

NOTE—*16 Cyg B is a known solar-type variable with low-amplitude modes (smaller than the limits reported here) at periods near 8 minutes (see Metcalfe et al. 2012). $A_{<1d}^{max}$ is the maximum amplitude peak seen in the periodogram less than 1 day. $V_{99.7}$ is peak to peak flux change of those relative fluxes that lie within 99.7% of the median flux.

[†]CROWD comes from the CROWDSAP estimate from the TESS SPOC pipeline and is the fraction of the flux that comes from the target star in the extracted aperture, as opposed to nearby sources in the TIC.

and has revealed peak-to-peak changes in flux as large as 1.4% for four of the JWST candidate calibrators. Another 11 show lower amplitude variability. This variability appears to arise from either stellar pulsations or stellar spots rotating in and out of view. At the same time, relative photometry from TESS has set upper limits on optical to near-infrared variability for most of the candidate standard stars at a level well below that needed to achieve the spectrophotometric requirements for JWST. Identifying those with known issues provides the JWST calibration team with information necessary to pick those stars with the highest likelihood of accurate calibrations in the least amount of observing time. This work has already led to revisions of the JWST spec-

525 trophotometric calibration star list, see Gordon et al. 526 (2022).

Some of the stars vetted in this paper are the same stars that were used to calibrate telescopes such as Spitzer (Reach et al. 2005) and Hubble (Bohlin et al. 2011), and some may be used to calibrate future space and ground-based telescopes. Because TESS is an onsoing all-sky survey, in the future TESS will serendipitously continue to monitor many of the JWST spectrophotometric calibration stars. This monitoring by TESS will reveal if the star varies photometrically in new or unexpected ways. Some of these observations may even be contemporaneous with the JWST calibration observations, as both missions plan to be operating

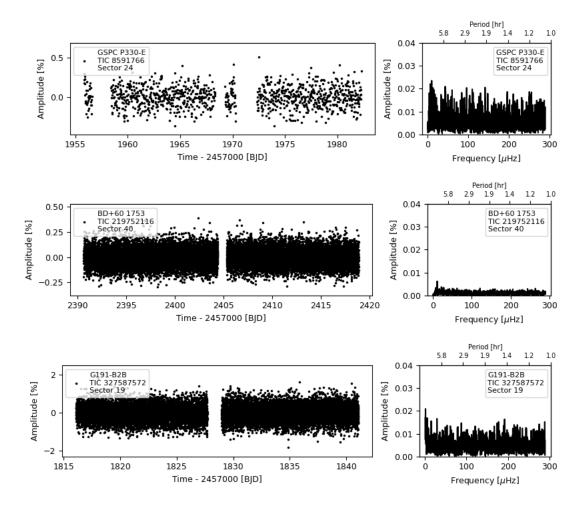

Figure 6. Light curves and Lomb-Scargle periodograms of three common calibration stars that show no significant, coherent variability in the TESS light curves.

539 at the same time. This work provides further evidence 540 that small NASA missions like TESS can provide cru-541 cial supporting observations which enable larger mis-542 sions like JWST to accomplish their science goals.

This paper includes data collected by the TESS mission. Funding for the TESS mission is provided by NASA's Science Mission Directorate. We thank the STScI internship program and JWST for providing funding for MK. JJH acknowledges financial support through NASA Award 80NSSC20K0592. This research has made use of the VizieR catalogue access tool, CDS, Strasbourg, France (DOI: 10.26093/cds/vizier). The original description of the VizieR service was published in A&AS MAST archive for access to the TESS light curves, target pixel files, and TESS Input Catalog.
